

## Abstract

Using Ekman pumping rates mediated by sea-ice in the Arctic Ocean’s Beaufort Gyre (BG), the magnitude of lateral eddy diffusivities required to balance downward pumping is inferred. In this limit — that of vanishing residual-mean circulation — eddy-induced upwelling exactly balances downward pumping. The implied eddy diffusivity varies spatially and decays with depth, with values of 50–400 m<sup>2</sup> s<sup>-1</sup>. Eddy diffusivity estimated using mixing length theory applied to BG mooring data exhibits a similar decay with depth and range of values from 100 m<sup>2</sup> s<sup>-1</sup> to more than 600 m<sup>2</sup> s<sup>-1</sup>. We conclude that eddy diffusivities in the BG are likely large enough to balance downward Ekman pumping, arresting the deepening of the gyre and suggesting that eddies play a zero-order role in buoyancy and freshwater budgets of the BG.

## 1 Introduction

The Arctic Ocean’s Beaufort Gyre, centered in the Canada Basin, is characterized by a strong halocline stratification with relatively fresh surface waters overlying saltier (and warmer) waters of Atlantic Ocean origin. The halocline stratification inhibits the vertical flux of ocean heat to the overlying sea-ice cover. The halocline is deepened by Ekman pumping associated with a persistent but highly variable Arctic high pressure system [Proshutinsky and Johnson, 1997; Proshutinsky et al., 2009, 2015]. This creates the anticyclonic Beaufort Gyre (BG) in which salinity surfaces bow downwards creating a bowl of freshwater, the main reservoir of freshwater in the Arctic.

Due to the store of available potential energy associated with its tilted isopycnal surfaces, the BG is highly susceptible to baroclinic instability and indeed a ubiquitous mesoscale eddy field is a notable feature of observations [Manley and Hunkins, 1985; Timmermans et al., 2008; Zhao et al., 2014, 2016].

Through idealized modeling studies, the mesoscale eddy field, which includes coherent eddies (of order 10 km in diameter) as well as fluctuations on order 100 km scales [Nurser and Bacon, 2014], has been implicated in playing a key role in equilibrating the freshwater budget of the BG [Manucharyan et al., 2016; Manucharyan and Spall, 2016]. However it is difficult to quantify the importance of the eddy field in the large-scale dynamics directly from observations. This quantification and an assessment of the contribution of the eddy induced circulation to the dynamics of the BG are the main goals of the present study.

Here we apply a residual-mean framework to examine whether observations in the BG are consistent with eddies playing a leading order role in the dynamics and transport. The residual-mean circulation is the sum of the mean flow (i.e., the Eulerian-mean circulation) plus transport by eddies (i.e., the bolus transport). This decomposition has proven effective, for example, for understanding Southern Ocean dynamics [Danabasoglu et al., 1996; Marshall and Radko, 2003; Marshall and Speer, 2012]. In the Southern Ocean the wind-driven Deacon Cell is largely balanced by a mesoscale eddy-induced overturning cell, and the residual-mean circulation vanishes.

We test the hypothesis that wind driving of the large-scale anticyclonic BG circulation is balanced by eddy fluxes (bolus fluxes). In this balance (shown schematically by black arrows in Figure 1), the residual-mean circulation is zero and a relationship may be derived between lateral eddy diffusivity  $K_D$ , surface-ocean stress, and isopycnal slopes of the large-scale gyre. Observations of the latter two then allow for estimates of  $K_D$ . We go on to compare the spatial patterns and magnitudes of the diffusivities to those computed directly using mixing length theory applied to timeseries from four moorings deployed in the BG.

The paper is set out as follows. In Section 2 we describe BG observations and wind forcing used in the analysis. In Section 3, guided by residual-mean theory, we infer BG halocline eddy diffusivities required to bring the BG residual flow to zero. In Section 4 we show

44 **Figure 1.** Schematic of the hydrography and circulation of the Beaufort Gyre, fresh (blue) at the surface  
 45 and salty (red) below. The grey arrows represent the anticyclonic forcing of the gyre by the prevailing winds.  
 46 The top black arrow represents freshwater being gathered towards the center of the gyre by wind-driven Ek-  
 47 man transport, the convergence of which pumps down into the center of the gyre. This causes salinity surfaces  
 48 to bow downward into the interior, deep in the center and shallow on the periphery of the gyre. The baroclinic  
 49 instability of the gyre has the tendency to flatten salinity surfaces and results in an eddy bolus flux (black  
 50 arrow at depth) of freshwater directed outward from the center, offsetting the inward flux at the surface.

69 that these estimates are similar to those deduced from mooring data. In Section 5 we con-  
 70 clude with a discussion of the implications of our study.

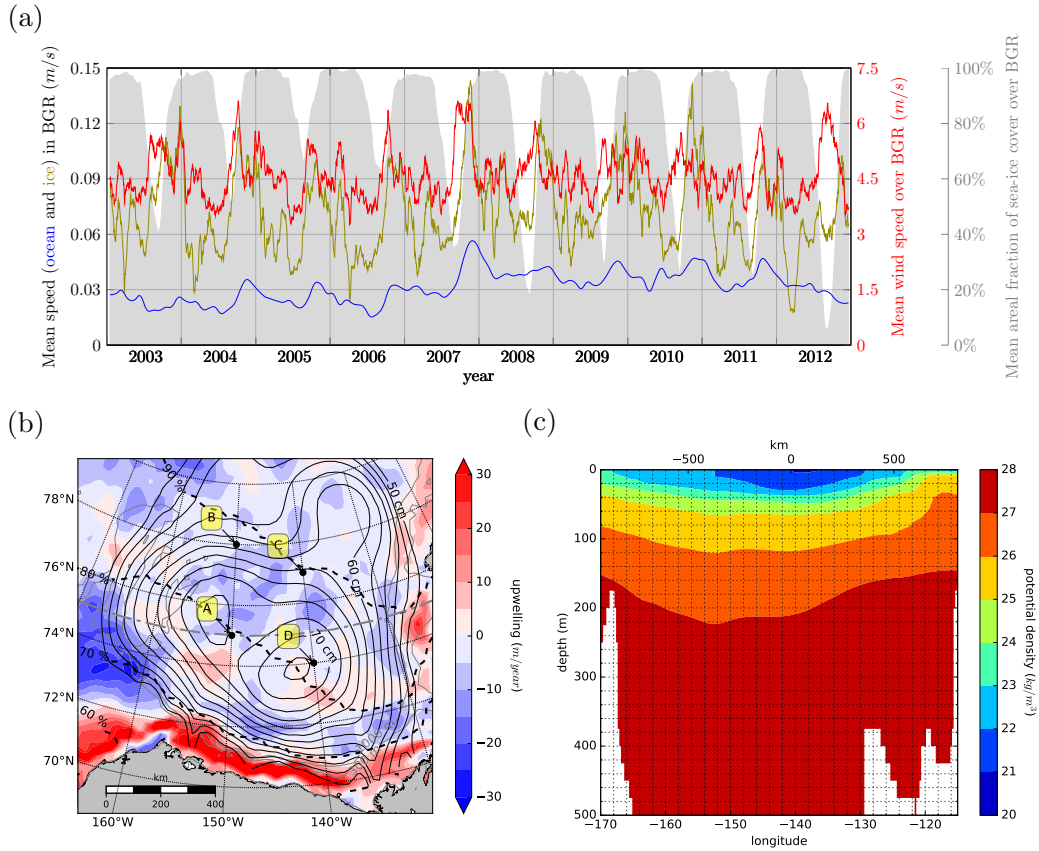

## 71 2 Observed structure of the Beaufort Gyre and wind forcing

82 To estimate the air-ocean and ice-ocean stress  $\tau$  and Ekman pumping  $w_{Ek} = \frac{\nabla \times \tau}{\rho_0 f_0}$ ,  
 83 we follow the approach of Yang [2006, 2009]. We use  $\rho_0 = 1027.5 \text{ kg m}^{-3}$  as a reference  
 84 density for water and  $f_0 = 1.46 \times 10^{-4} \text{ s}^{-1}$  as the Coriolis parameter. The mean surface  
 85 stress  $\tau$  is computed by averaging daily surface stresses, obtained as a combination of ice-  
 86 ocean and air-ocean surface stresses, each estimated using a quadratic drag law with fixed  
 87 drag coefficients ( $C_{Dice} = 0.0055$ ,  $C_{DAir} = 0.00125$ ), and weighted by the observed local ice  
 88 concentration  $\alpha$ :

$$\tau = \alpha \underbrace{\rho_0 C_{Dice} |\mathbf{u}_{rel}| (\mathbf{u}_{rel})}_{\tau_{ice}} + (1 - \alpha) \underbrace{\rho_{air} C_{DAir} |\mathbf{u}_{air}| (\mathbf{u}_{air})}_{\tau_{air}}, \quad (1)$$

89 where  $\mathbf{u}_{rel} = \mathbf{u}_{ice} - (\mathbf{u}_{geo} + \mathbf{u}_{Ek})$  is the relative velocity between the ice and ocean. We  
 90 choose to use a reference velocity  $\mathbf{u}_{geo} + \mathbf{u}_{Ek}$ , representing the ocean velocity near the ice  
 91 surface. Shallow and deeper reference levels can be used [Lu *et al.*, 2011]. Sensitivity to the  
 92 choice of the drag coefficient's value is discussed in §3. The air density is taken as  $\rho_{air} =$   
 93  $1.25 \text{ kg m}^{-3}$ .

94 To evaluate equation (1) we combine four datasets: (i) sea ice concentration  $\alpha$  from  
 95 Nimbus-7 SMMR and DMSP SSM/I-SSMIS Passive Microwave Data Version 1 [Cavalieri  
 96 *et al.*, 1996]; (ii) sea ice velocity  $\mathbf{u}_{ice}$  from the Polar Pathfinder Daily 25 km EASE-Grid Sea  
 97 Ice Motion Vectors, Version 3 [Tschudi *et al.*, 2016]; (iii) surface geostrophic currents  $\mathbf{u}_{geo}$   
 98 computed from Dynamic Ocean Topography [Armitage *et al.*, 2016, 2017] and (iv) 10 m  
 99 wind  $\mathbf{u}_{air}$  from the NCEP-NCAR Reanalysis 1 [Kalnay *et al.*, 1996]. The 2003-2012 tem-

72 **Figure 2.** (a) Thirty-day running mean of sea-ice speed (green), surface geostrophic current speed (blue)  
 73 and 10 m wind speed (red) over the Beaufort Gyre Region, delimited by 70.5°N-80.5°N and 170°W-130°W  
 74 and including only locations with depths greater than 300 m [Proshutinsky *et al.*, 2009]. The gray shading  
 75 represents mean areal fraction of sea-ice cover. The white annual downward spikes correspond to the sum-  
 76 mertime with progressively less ice cover over time, particularly in 2012. (b) The 2003-2012 climatology of  
 77 Ekman pumping  $w_{Ek}$  (color) and geopotential height  $D$  computed from the 2005-2012 World Ocean Atlas  
 78 (WOA) climatology (black contours, see §3); the location of the four Beaufort Gyre Observing System moor-  
 79 ings (named A, B, C and D) are marked by black dots. Thick dashed lines show mean ice concentration. (c)  
 80 hydrographic section of potential density (referenced to the surface) at 75°N (see gray dash-dotted line in  
 81 panel (b)), computed from the WOA climatology.

poral variability of these four variables (mean values over the Beaufort Gyre) is summarized in Figure 2a.

Our estimate of the surface ocean current  $\mathbf{u}_{geo} + \mathbf{u}_{Ek}$  differs from Yang [2006, 2009], however, in two key ways. First, we use the Ekman velocity at the surface (rotated  $45^\circ$  to the right of the surface stress) in place of the mean Ekman transport velocity ( $90^\circ$  from the surface stress), thus  $\mathbf{u}_{Ek} = \tau \frac{\sqrt{2}e^{-\frac{z}{D_e}}}{f_0\rho_0 D_e}$ , with  $D_e = 20$  m [Yang, 2006]. Because the Ekman velocity and the surface stress depend on each other, equation (1) is solved iteratively. Second, and more importantly, we include the surface geostrophic current  $\mathbf{u}_{geo}$  inferred from dynamic ocean topography [Armitage *et al.*, 2016, 2017]. Similar results can be obtained using geopotential height to estimate  $\mathbf{u}_{geo}$  [McPhee, 2013]. The geostrophic current speed approximately doubled after 2007 (Figure 2a, blue line), and we find that its inclusion has a non-negligible influence on Ekman pumping rates.

The 2003-2012 average Ekman pumping field inferred from observations (Figure 2b, color) depends on the prevailing winds and basin geometry, the distribution, drift speed and concentration of sea ice, and the strength of surface currents. We infer average downwelling rates of order  $5 \text{ m yr}^{-1}$  within the BG region, but there is considerable spatial structure. Strong upwelling speeds, in excess of  $30 \text{ m yr}^{-1}$ , can be seen in the coastal areas south of the 300 m bathymetric contour. Northwards of this downwelling rates reach  $20 \text{ m yr}^{-1}$  corresponding to a mean sea-ice concentration between 65% and 75%. For larger mean ice concentration, the BG Region is characterized by lower downwelling rates of order  $5 \text{ m yr}^{-1}$ , with localized patches of upwelling of maximum  $10 \text{ m yr}^{-1}$  around  $74^\circ\text{N}$ . Note however that our computations of eddy diffusivity described below depend on integrals over closed geostrophic contours and so do not depend on many of these details.

We remark that, as a consequence of the inclusion of the surface geostrophic current, our Ekman pumping field differs considerably in both intensity and spatial structure from previous results, as can be deduced by comparing Figure 2b with the results of Yang [2006, 2009] or MCPhee [2013]. A more detailed discussion is provided by [Meneghello, G., J. Marshall, M. L. Timmermans, and J. Scott (2017), Observations of seasonal upwelling and downwelling in the Beaufort Sea mediated by sea ice, *Journal of Physical Oceanography*, in revision].

The hydrographic structure of the BG, based on the quarter-degree resolution 2005-2012 World Ocean Atlas Climatology [Locarnini *et al.*, 2013; Zweng *et al.*, 2013], is summarized by contours of geopotential height

$$D = \frac{1}{g} \int_0^{p_0} [\rho^{-1}(S, T, p) - \rho^{-1}(35, 0, p)] dp, \quad (2)$$

where  $\rho^{-1}$  is the specific volume and  $p_0 = 400$  dbar (Figure 2b), and by a section of potential density across  $75^\circ\text{N}$  (Figure 2c). Potential density increases rapidly from  $1022 \text{ kg m}^{-3}$  to  $1027 \text{ kg m}^{-3}$  over the halocline in the top 300 m to join the very weakly stratified waters below. As expected from the pattern of Ekman pumping being imposed by the wind from above, isopycnals are deeper in the middle of the BG, with slopes of the order of 50 m over 500 km or less. This hydrographic structure supports, through thermal wind, the large-scale anticyclonic circulation of the gyre and is essential to our estimates of the eddy diffusivity required to balance the effect of the Ekman pumping, as outlined in the next section.

### 3 Eddy diffusivities in the limit of vanishing Residual Circulation

Adopting a residual mean theory framework [Andrews and McIntyre, 1976; Marshall and Radko, 2003; Plumb and Ferrari, 2005], we now use the observations of Ekman pumping and isopycnal slopes presented in section 2 to infer the magnitude of the eddy diffusivities required to bring the residual circulation in the halocline of the BG to zero. This is the limiting case analogous to the ‘vanishing of the Deacon Cell’ in the literature on Southern Ocean dynamics reviewed by Marshall and Speer (2012).

We integrate azimuthally along geopotential height contours shown in Figure 2b to represent the overturning circulation in the  $(r, z)$  plane by a streamfunction:  $(v_r, w) = \left(-\frac{\partial \Psi}{\partial z}, \frac{\partial \Psi}{\partial r}\right)$ , where  $r$  is a radial coordinate. In the assumed adiabatic interior of the halocline, we consider the limit case that the streamfunction describing the residual-mean circulation is vanishingly small:

$$\Psi_{res} = \bar{\Psi} + \Psi^* = 0, \quad (3)$$

where the Eulerian-mean streamfunction is given by the Ekman transport,  $\bar{\Psi} = \bar{\tau}/(\rho_0 f_0)$ , and the eddy-induced streamfunction is given by  $\Psi^* = \bar{v}'_r b' / \bar{b}_z$ , where  $\bar{v}'_r b'$  is the radial eddy buoyancy flux and  $\bar{b}_z$  is the vertical stratification. Overbars denote time and along-geopotential-height-contour averages. We are computing, then, the limit case in which bolus transport by eddies are sufficiently strong to exactly balance the Eulerian-mean flow set up by the wind.

As is conventional (see Gent and McWilliams, 1991) we characterise the efficiency of eddy transport by an eddy diffusivity and write,  $\bar{v}'_r b' = -K_D \bar{b}_r$ , and so  $\Psi^* = -K_D \bar{b}_r / \bar{b}_z$ . Adopting this closure as our definition of diffusivity, Eq.(3) provides a relationship between the wind stress  $\bar{\tau}$ , the mean buoyancy variations  $\bar{b}_r$  and  $\bar{b}_z$ , and the eddy diffusivity  $K_D$

$$K_D = \frac{1}{\rho_0 f_0} \frac{\bar{\tau}}{\bar{s}} \quad \text{where} \quad \bar{s} = -\frac{\bar{b}_r}{\bar{b}_z} = \frac{\partial \bar{h}}{\partial r}. \quad (4)$$

Here  $h$  is the depth of the isopycnal,  $r$  is the radial coordinate and  $\bar{s}$  the slope of the isopycnal of the time and azimuthally averaged density field. For computational convenience, rather than integrating along geopotential height contours, we use the divergence and Stokes theorems to rewrite (4) as

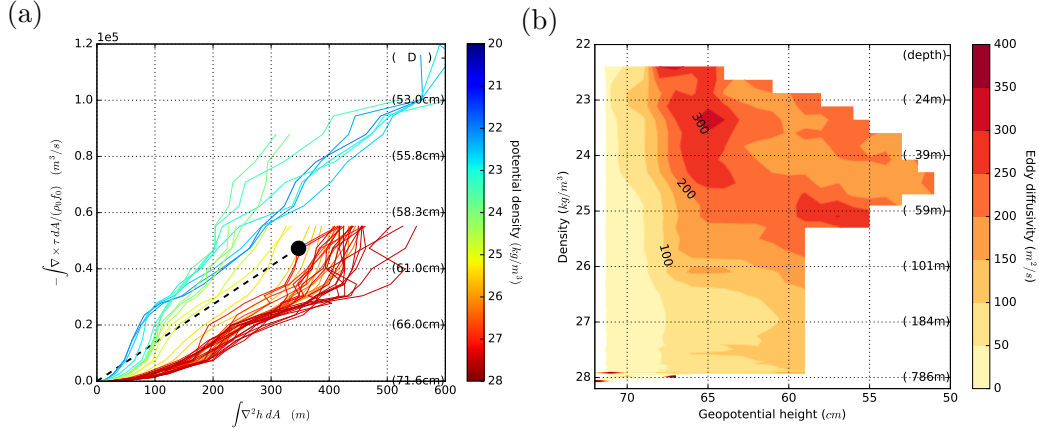

$$K_D = \frac{1}{\rho_0 f_0} \frac{\int \nabla \times \tau \, dA}{\int \nabla^2 h \, dA}, \quad (5)$$

where the integrals are performed over the area circumscribed by a geopotential height contour and limited to regions with depth greater than 300 m, and  $\tau$  and  $h$  are averaged only in time. The integrated Ekman pumping (in  $\text{m}^3 \text{s}^{-1}$ ) and thickness flux (m), i.e. the numerator and denominator of (5) respectively, are plotted in Figure 3a for different density levels.

The estimated eddy diffusivity, ranging from  $50 \text{ m}^2 \text{ s}^{-1}$  to  $400 \text{ m}^2 \text{ s}^{-1}$ , is plotted as a function of geopotential height and density in Figure 3b. We observe a strong dependence on the density level and on the geopotential height contour: higher values of eddy diffusivity are concentrated in the top 100 m from the surface (lighter than  $26 \text{ kg m}^{-3}$ , see also Figure 2c) and close to the 65 cm geopotential height contour, and decay by a factor of four at greater depth and towards the center of the gyre. White areas in Figure 3b correspond to outcropping isopycnals above  $25 \text{ kg m}^{-3}$  and/or to the presence of land in at least one point along the dynamic height contour below that.

We remark that uncertainty in the evaluation of the numerator and denominator of (4) is large. There are errors in our estimates of stress due to uncertainties in Ekman layer thickness  $D_e$ , the drag coefficients  $C_{Dice}$  and  $C_{Dair}$  as well as in the accuracy of the estimated ice, wind and ocean surface velocities. As an example, decreasing (increasing) the Ekman layer thickness from 20 m [Yang, 2006] to 10 m (40 m) [Cole *et al.*, 2017] results in a decrease (increase) of the estimated eddy diffusivity by approximately 20%. Similarly, there are uncertainties in the ice-ocean drag coefficient  $C_{Dice}$ , which can vary between 0.001 and 0.01 depending on ice roughness, concentration and many other factors [Lu *et al.*, 2011; Cole *et al.*, 2017]. A possibly even larger source of uncertainty is associated with the wind, ice and ocean velocities used in (1). Before we go on we should note that if the mean Ekman pumping over the region were  $10 \text{ m yr}^{-1}$  instead of  $5 \text{ m yr}^{-1}$ , the eddy diffusivity required to bring the residual flow to zero would be doubled.

The values of  $K_D$  shown in Figure 3 are those required to exactly balance Ekman processes. How do eddy diffusivities inferred from observations compare with those inferred by

171 **Figure 3.** (a) Integrated Ekman pumping (in  $\text{m}^3 \text{s}^{-1}$ ) plotted against the integrated  $\nabla^2 h$  (in m) at different  
 172 density levels as indicated by color. The resulting eddy diffusivity  $K_D$  can be readily obtained as the ratio  
 173 of the two values; for the point marked with a black dot, this is equivalent to the slope of the dashed line  
 174 (in  $\text{m}^2 \text{s}^{-1}$ ). (b) Eddy diffusivity  $K_D$  as a function of density and geopotential height contour; the depth in  
 175 parenthesis is the mean depth of the isopycnal.

198 assuming zero residual flow? To explore we now estimate lateral diffusivity using an entirely  
 199 different method making use of hydrographic and current meter data.

#### 200 4 Estimates of eddy diffusivities from mooring data

205 Horizontal eddy diffusivity is estimated from temperature, salinity and velocity profiles  
 206 obtained from four Beaufort Gyre Observing System (BGOS) moorings, whose position are  
 207 shown in Figure 2b.

208 Each mooring provides a pair of profiles spanning  $\approx 50$  m to 2000 m depth every 54  
 209 hours. Each pair of profiles is separated by 6 hours in time so that averaging minimizes the  
 210 influence of near-inertial motions that have an approximately 12 hour period. Processed data  
 211 have a 2 m vertical resolution. Data are utilized over August 2003 to August 2012, with each  
 212 mooring having some years in which data were not returned (e.g., mooring A: July 2006  
 213 – Aug 2007 and July 2008 – September 2009). The record at mooring C ended in August  
 214 2007.

215 A mixing length framework is employed as described by *Cole et al.* [2015]. The mix-  
 216 ing length,  $\lambda$ , and horizontal diffusivity,  $K_\lambda$ , are estimated as:

$$\lambda = \frac{\overline{\theta'_{iso} \theta'_{iso}}^{1/2}}{|\nabla \theta_{iso}|} \quad (6)$$

$$K_\lambda = c_0 \lambda \overline{u'u'}^{1/2}, \quad (7)$$

217 where  $\theta_{iso}$  is the temperature along a density surface,  $u$  the horizontal velocity vector, and  
 218  $c_0$  a mixing efficiency [Tennekes, 1972; Armi and Stommel, 1983; Naveira Garabato et al.,  
 219 2011; Abernathey and Cessi, 2014]. The mixing efficiency is taken to be  $c_0 = 0.16$  [Wunsch,  
 220 1999; Klocker and Abernathey, 2014]. Primed quantities denote a fluctuation from the mean;  
 221 temperature and velocity were first averaged with a 30-day timescale, and then all variability  
 222 at timescales larger than one year was removed. The timescales are chosen to exclude higher

201 **Figure 4.** Profiles of a) mixing length, b) magnitude of velocity fluctuations, and c) along-isopycnal eddy  
 202 diffusivity  $K_\lambda$  at the four BGOS moorings. The black thick line denotes the mean among the four moorings.  
 203 Extraneous mixing lengths at moorings A and D (red and blue) over 200-250 m depth are excluded from the  
 204 diffusivity calculation (see text).

223 frequency variability primarily in the velocity observations, and to represent the mesoscale  
 224 dynamics of the system. Overbar denotes a temporal average over all years. The spatial gra-  
 225 dient of the mean temperature field,  $\nabla\bar{\theta}_{iso}$ , is estimated along density surfaces from MIMOC  
 226 [Schmidtke *et al.*, 2013] at a 100 km scale. The calculation is performed independently on  
 227 each density surface and for each mooring. Only the upper 600 m are presented here.

228 The mixing length framework assumes that temperature and salinity anomalies along a  
 229 density surface are determined by horizontal processes, and that vertical processes are neg-  
 230 ligible. Two of the moorings, A and D, fail this criteria in the 200-250 m depth range where  
 231 horizontal gradients are very small; these regions lead to an elevated mixing length (Fig-  
 232 ure 4a), and are excluded from the horizontal diffusivity estimate (Figure 4c).

233 A range of mixing lengths, velocity fluctuations, and diffusivities were found at the  
 234 four moorings (Figure 4). Mixing length values ranged from less than 50 to near 200 km.  
 235 Velocity fluctuations decayed by more than a factor of two between 70 m and 300 m depth,  
 236 and then remained constant at approximately  $0.02 \text{ m s}^{-1}$ . Both mixing length and velocity  
 237 fluctuations are small in comparison to other regions [Cole *et al.*, 2015]. Eddy diffusivities  
 238 ranged from 100 to more than  $600 \text{ m}^2 \text{ s}^{-1}$ , with a factor of two decay with depth from 70 to  
 239 300 m arising from that of the velocity fluctuations. There was significant variability in all  
 240 quantities between the moorings, with mooring B having elevated mixing lengths, velocity  
 241 fluctuations, and diffusivity at all depths due to its proximity to the basin boundary and the  
 242 Chukchi Plateau, a source of eddies that transit past mooring B [Carpenter and Timmermans,  
 243 2012].

244 There are considerable uncertainties in our evaluation of  $K_\lambda$ . The mixing length is not  
 245 always well conditioned, as seen for example for moorings A and D. Eddy kinetic energy  
 246 depends on the period over which the cutoff is applied; here we have chosen 30 days, but  
 247 higher EKE is obtained for higher frequency cutoffs. As an example, a 7 days cutoff (which  
 248 would capture more eddies) results in an approximately 30% larger EKE and eddy diffusiv-  
 249 ity. The value of  $c_0$ , here set to 0.16, depends on the decorrelation timescale of the eddies  
 250 which could very well be different in the Arctic from elsewhere. Nevertheless, despite the

251 uncertainties in our estimates of  $K_\lambda$  and  $K_D$ , they are broadly similar to one-another both in  
 252 magnitude and in their vertical structure.

## 253 5 Discussion and implications

254 Guided by residual mean theory and the observed structure of the halocline in the BG,  
 255 we have mapped out the magnitude and spatial pattern of eddy diffusivity required to exactly  
 256 balance the Eulerian-mean flow set up by winds (Ekman processes mediated by ice) blow-  
 257 ing over the surface. We find eddy diffusivities  $K_D$  that vary from order  $400 \text{ m}^2 \text{ s}^{-1}$  at the  
 258 surface decaying rapidly over the halocline to order  $50 \text{ m}^2 \text{ s}^{-1}$  at a depth of 300 m or so, and  
 259 close to the center of the gyre. We remark that both the eddy diffusivity value and its spatial  
 260 structure are in broad agreement with results from eddy resolving numerical simulation by  
 261 *Manucharyan et al.* [2016] (see Figure 3 of that paper).

262 Estimates of eddy diffusivity  $K_\lambda$ , employing mixing length theory based on BG moor-  
 263 ing measurements, are at least as large as  $K_D$ , with broadly the same vertical structure. De-  
 264 spite the significant uncertainties in both estimates of  $K_\lambda$  and  $K_D$  outlined at the end of §3  
 265 and §4, our results indicate that the eddy-induced transport in the BG is of the same order of  
 266 magnitude as that required to balance the accumulation of freshwater by Ekman pumping,  
 267 estimated using an ocean surface stress climatology.

268 This suggests that the residual flow is small in the halocline of the Beaufort Gyre, and  
 269 has the following implications:

- 270 1. freshwater, heat and tracer transport in the BG, which is achieved by the residual flow,  
 271 is likely very different from that based on the Eulerian mean circulation, the quantity  
 272 conventionally mapped from observations.
- 273 2. the small residual overturning circulation implies a scaling  $H \approx \frac{R\tau}{\rho_0 f_0 K_D}$  for the depth  
 274 of the halocline (from Eq.4 where  $R$  is the radius of the gyre. This is the scaling for  
 275 the depth of the thermocline in the ACC postulated by *Marshall and Radko* [2003]  
 276 and the depth of the halocline found by *Manucharyan et al.* [2016] and *Manucharyan*  
 277 *and Spall* [2016] in their idealized models of the BG.
- 278 3. models of the Arctic require a mesoscale parameterization with diffusivities around  
 279  $500 \text{ m}^2 \text{ s}^{-1}$  decaying over the depth of the halocline to small values in the abyss.
- 280 4. how models respond to a change in the wind may be dependent on how they parame-  
 281 terize mesoscale eddies, since eddies play a zero-order role in mediating the freshwa-  
 282 ter budget of the gyre.

283 Finally, it should be said that the present analysis is not exhaustive, and other mecha-  
 284 nisms may influence the BG dynamics. Several processes may contribute to setting or mod-  
 285 ifying the observed Ekman pumping rate, e.g., vertical mixing of halocline waters or up-  
 286 welling in winter driven by the interaction of the geostrophic current with winter fast ice.  
 287 The analysis of the relative importance of such seasonal upwelling versus eddy diffusivity in  
 288 deflating the gyre is the subject of a follow up paper. Regardless of the specific mechanisms  
 289 that may contribute to the annually averaged Ekman pumping rate, eddy bolus fluxes are ca-  
 290 pable of balancing this observed Ekman pumping. Future work should additionally attempt  
 291 to more precisely constrain the estimates presented here. One possibility would be to carry  
 292 out a tracer release in the halocline of the BG following the example of the DIMES experi-  
 293 ment [*Gille et al.*, 2012] in the Southern Ocean. The rates of lateral and vertical dispersion  
 294 can then yield direct information about mesoscale eddy stirring rates and diapycnal mixing  
 295 rates.

NCEP Reanalysis data provided by the NOAA/OAR/ESRL PSD, Boulder, Colorado, USA, from their Web site at <http://www.esrl.noaa.gov/psd/> [Kalnay *et al.*, 1996]

Arctic dynamic topography data were provided by the Centre for Polar Observation and Modelling, University College London [www.cpom.ucl.ac.uk/dynamic\\_topography](http://www.cpom.ucl.ac.uk/dynamic_topography) [Armitage *et al.*, 2016]

BG mooring data were collected and made available by the Beaufort Gyre Exploration Program based at the Woods Hole Oceanographic Institution (<http://www.whoi.edu/beaufortgyre>) in collaboration with researchers from Fisheries and Oceans Canada at the Institute of Ocean Sciences. Data are online at: <http://www.whoi.edu/website/beaufortgyre/data>.

All data for this paper is properly cited and referred to in the reference list.
